ECE 132A: Final Project 2

Text Transmission Over the Air (Python implementation)

Setup and original code-

The provided github code delivers bits via audible tones using quaternary FSK (four carrier frequencies) duplicated over two channels. The receiver and emitter codes use different Python libraries to manipulate audio for some reason, but after installing everything the setup was extremely simple. Their code transmits all 163 ASCII characters (8 bits each) and the 13-bit barker in 69 seconds for a bit rate of $R_b = 19\text{Hz}$. For the terminal outputs for a clear transmission, a transmission with AWGN in the 1-2 kHz range (corrupting one channel), and a transmission with AWGN in the 2-3 kHz range (corrupting the other channel), see **Figure 1**. Testing the code against noise was more difficult than I expected because, at the point where either channel can be corrupted by the noise, the transmission is barely audible to human ears.

there are no extraneous characters, this transmission was actually error-free!]
```

Figure 1- Quaternary FSK Signaling: The responses to clear transmission, 2-3 kHz interference, and 1-2 kHz interference are shown from top to bottom respectively. The received test characters (emitted as ‘_t_’) are decoded from each channel and printed first to indicate corruption.

Redesigning for octonary transmission-

After familiarizing myself with the code, I noticed that the designers had spectral resolution to spare. Hoping that it may spare future students (and the roommates of future students) a few unnecessary seconds of computer beeping during Week 10, I decided to expand the code into an octonary FSK system.

To facilitate increased complexity, I replaced the nested if/else structure with a dictionary implementation. This directly associated frequency bins from both channels with their respective bit representations. Then I adjusted the signal length and bit indexing to accommodate 3-bits per carrier frequency, including extending the text file to 162 characters (to allow dividing bits into groups of three). I also had to spend some time debugging the receiver-side audio sample indexing. After ironing out the bugs, the updated code delivers 165 characters and a 15-bit barker in 47 seconds, yielding the expected bit rate of $R_b' = 1.5R_b = 28\text{Hz}$. Maybe their professor will give me extra points for the quick and accurate transmission. The responses of my version to clear and noisy transmissions are shown in **Figure 2**.

there are zero extraneous characters, this transmission was actually error-free!
```

Figure 2- Octonary FSK Signaling: The same corruption from the filters is visible here, but the other channel maintained accuracy.

Other optimizations-

I also tried increasing the bit rate by decreasing the period between carrier switches (I increased F_{bit} from 10 to 15). Although rapid jumps in frequency do introduce some distortion (in the form of slight clicking noises) from my laptop speakers at some point, I was able to

produce accurate decodings from a 31-second transmission. This puts my system at $R_b'' = 43$ Hz, and I'm sure we could push it further. See **Figure 3** for its performance.

```

Figure 3- Transmission Accuracy At Doubled Bitrate: This system runs at over twice the bitrate of the original system. However, by decreasing the frame size I have also decreased the spectral resolution, which could cause problems distinguishing one carrier from the next if taken too far. At this point there's some risk of losing points for accuracy.

Conclusion-

This project solidified my understanding of FSK signaling by turning a rather abstract concept (light frequencies) into something easy to conceptualize (like audio), demonstrated the constant trade-off between accuracy and bandwidth, and I consider it a success.

All code is available at https://github.com/sudo-quinnmaloney/transmit_text_via_audio; see the original project at https://github.com/Mortiniera/text_transfert_over_audio_channel.
